Abstract

In this paper we introduce two procedures for variable selection in cluster analysis and classification rules. One is mainly oriented to detect the "noisy" non–informative variables, while the other deals also with multicolinearity. A forward–backward algorithm is also proposed to make feasible these procedures in large data sets. A small simulation is performed and some real data examples are analyzed.

Keywords: Cluster Analysis, Selection of variables, Forward-backward algorithm.

1 Introduction

In multivariate analysis there are several statistical procedures whose output is a partition of the space. Typical examples of this situation are cluster

[1]Corresponding author: Ana Justel, Departamento de Matemáticas, Universidad Autónoma de Madrid. Campus de Cantoblanco, 28049 Madrid, Spain. Email: ana.justel@uam.es

analysis and classification rules. In cluster analysis (or un–supervised classification) we look for a partition of the space into homogeneous groups or clusters (with small dispersion within groups), that help us to understand the structure of the data. Several cluster methods have been proposed, such as hierarchical clustering (Hartigan, 1975), k-means (MacQueen, 1967), k-mediods (Kaufman and Rousseeuw, 1987), kurtosis based clustering (Peña and Prieto, 2001). From most of them we get a partition of the space in disjoint subsets.

Pattern recognition or classification is about guessing or predicting the unknown nature of an observation, a discrete quantity such as black or white, one or zero, sick or healthy. An observation is a collection of numerical measurements such as an image (which is a sequence of bits, one per pixel), a vector of weather data, or an electrocardiogram. In classification rules, we have in addition a training sample for each group, from which we know together with the observation of the random vector of variables, a label that indicates to which subpopulation it belongs. Then a *classifier* is any map that represents for each new data our guess of the class, given its associated vector. The map produces a classification rule, that is also a partition of the space. According to which subset of the partition a new data belongs, is classified in that class. There is also an extensive literature on classification rules, such as Fisher's linear discrimination (Fisher, 1936), nearest neighbor rules (Fix and Hodges, 1951), regression trees-CART (Breiman et al., 1984), or reduced kernel discriminant analysis (Hernández and Velilla, 2005).

A general problem in cluster or classification is to find structures in a high dimensional variable space but with small data sets. It is common that in many practical cases, the amount of variables (that should not be confused with the amount of information) is too high. This may be due to the presence of several "noisy" non–informative variables, and/or redundant information from strongly correlated variables that may produce multicolinearity. Then the information contained in the data set could be extracted from a reduced subset of the original variables.

A difficult task is to find out which variables are "important", where the concept of "important" should be related to the statistical procedure we are

dealing with. If we are interested in cluster analysis, we would like to find the variables that explains the groups we have found. In this way, a (small) subset of variables should "explain" as best as possible the statistical procedure in the original space (the high dimensional space). Dimension reduction techniques (like principal component analysis) will produce linear combinations of the variables which are difficult to interpret unless most of the coefficients of the linear combination are negligent. The variable selection method of Fowlkes, et al. (1988) shifts the problem to a reduced variable space and looks for new clusters with less variables. Tandesse, et al. (2005) propose a Bayesian approach for simultaneously selecting variables and identifying cluster structures without knowing the number of clusters. The Bayesian model with latent variables is very useful in cluster analysis since it produces the most complete output: number of clusters, data allocation and informative variables. To solve the model it is necessary to use MCMC methods, in particular Metropolis-Hastings with Reversible-Jump (Green, 1995), that introduce an important complexity to the users that are not familiar with computer programming.

In this paper we propose consistent statistical methods for variable selection that are easy to use. The variables that explain better the procedure on the original space help us to understand better the cluster output, and as a by-product, we find a dimension reduction procedure that can be used in a new data set for the same problem. We consider two different proposals based on the idea of "blinding" unnecessary variables. To cancel the effect of one variable, we substitute all the values of that variable by it's marginal mean in the first proposal and by the conditional mean in the second proposal. The marginal mean approach is mainly oriented to detect the "noisy" non–informative variables, while the conditional mean approach is more related to deal also with multicolinearity. The first one is simpler and does not require large sample size as the second one. In practice, we will also need an algorithm to solve the optimization problem.

In Section 2 we define in precise terms what we understand for a subset of variables that explains a multivariate partition procedure. Next we define our objective function and provide a strongly consistent estimate of the op-

timal subset. A small simulation study is also performed. In Section 3 we introduce the proposal based on the conditional mean and show the performance in a simulated data set. In Section 4 we describe a forward–backward selection algorithm that looks for the minimum subset that explains a fixed percentage of the data assignation to the clusters. Section 5 is devoted to the analysis of two real data examples with medium and large dimensional variable spaces. Section 6 includes some final remarks and the proofs are given in the Appendix.

2 Dropping out noise non–informative variables

Let $X = (X_1, \ldots, X_p)$ be a random vector with distribution P. We consider any statistical procedure whose output is a partition of the space R^p. For instance, this is the case of the population target for most clustering methods or classification rules. To fix ideas we will concentrate in cluster methods. For a fix number of clusters K, we have a function

$$f : R^p \to \{1, \ldots, K\}$$

which determines to which cluster each single point belongs. We denote the space partition by $G_k = f^{-1}(k),\ \ k = 1, \ldots, K$, that satisfies

$$P\left(\bigcup_{k=1}^{K} G_k\right) = 1.$$

For instance, if we consider $k - means$ (with K=2), and $c_1, c_2 \in R^p$ are the cluster centers, i.e. the values that minimize

$$E\left(\min(||X - c_1||^2, ||X - c_2||^2)\right),$$

the set G_1 is given by $G_1 = \{x \in R^p : ||x - c_1|| \leq ||x - c_2||\}$, while $G_2 = G_1^c$.

If p is large, typically some of the components of vector X are strongly correlated or might be almost irrelevant for the cluster procedure. Then, if the information from the noisy variables is removed from our data, we should

expect that their cluster allocations does not change. These means that the data are kept in the same group as in the original partition. The key point is to notice that the partition is defined in the original p-dimensional space and the input data requires information from all the variables, included the noisy ones. We propose to look for the subset of indices $I \subset \{1, \ldots, p\}$ for which the original partition rule applied to a new "less informative" vector $Y^I \in R^p$ built up from X, behaves as close as possible to the procedure when is applied to the "full information" vector X. The vector Y^I contains the variables from X that are index by I, and the rest of the variables with index outside the set I are "blinded". A noisy variable means that its probability distribution is almost the same at all the clusters. This suggests to substitute the information in the "blinded " variables by their mean value.

It will depend on the problem (the distribution P of X) and on how many variables $d < p$ we select, the percentage of cluster allocations explained by them. In practice, we can choose d in order to explain at least a fixed percentage, for instance, 90%, 95% or 100% of the data.

2.1 Population and empirical objective functions

We now put our purpose in a precise setup. Given a subset of indices

$$I = \{i_1, \ldots, i_d\} \subset \{1, \ldots, p\},$$

we define the vector $Y^I := Y = (Y_1, \ldots, Y_p)$, where $Y_i = X_i$ if $i \in I$ and $Y_i = E(X_i)$ otherwise. Note that instead of the expectation $E(X_i)$ we can use the median of X_i or any other location parameter for the i–coordinate like M-estimates or trimmed–means. The results will still holds provided we have a strong consistent estimate of the location parameter.

For a fixed integer $d < p$, the population target is the set $I \subset \{1, \ldots, p\}$, $\#I = \mathrm{d}$, for which the *population objective function*, given by

$$h(I) = \sum_{k=1}^{K} P\left(f(X) = k, f(Y^I) = k\right),$$

attains it maximum.

In this way, we look for the subset I for which the original partition rule applied to the less informative random vector Y^I behaves as close as possible to the procedure when is applied to the "full information" vector X. All components with index outside the set I are blinded in the sense that are constant.

In practice, the empirical version consist on the application of the next steps:

1. Given iid data $X_1, \ldots, X_n \in R^p$, apply the partition procedure to the data set and obtain the empirical cluster allocation function,

$$f_n : R^p \to \{1, \ldots, K\},$$

   where now $f_n(x)$ is data dependent. The associated space partition will be denoted by $G_k^{(n)} = f_n^{-1}(k)$, for $k = 1, \ldots, K$.

2. For a fixed value $d < p$, given a subset of indices $I \subset \{1, \ldots, p\}$, with $\#I = d$, define the random vectors $\{X_j^*, 1 \leq j \leq n\}$ verifying

$$X_j^*[i] = X_j[i] \text{ if } i \in I, \text{ and } X_j^*[i] = \bar{X}[i] \text{ otherwise,}$$

   where $X[i]$ stands for the i–coordinate of the vector X, and $\bar{X}[i]$ stands for the i–coordinate of the average vector.

   If we have used instead of the expected value other location parameter in the population version (like the median), we substitute the average by the empirical version (the sample median).

3. Calculate the *empirical objective function*

$$h_n(I) = \frac{1}{n} \sum_{k=1}^{K} \sum_{j=1}^{n} \mathcal{I}_{\{f_n(X_j)=k\}} \mathcal{I}_{\{f_n(X_j^*)=k\}},$$

   where $\mathcal{I}_A$ stands for the indicator function of the set A.

4. Look for a subset $I_{d,n} =: I_n$, with $\#I_n = d$, that maximizes the empirical objective function h_n.

2.2 Consistency. Assumptions and main result

As expected, the consistency of our variable selection procedure is linked to the properties of the cluster partition method. We now give some conditions under which our procedure is consistent.

Assumption 1:

a) The partition procedure is strongly consistent, i.e., given $\epsilon > 0$, there exists a set $A(\epsilon) \subset R^p$ with $P(X \in A(\epsilon)) > 1 - \epsilon$, such that for all $r > 0$

$$\lim_{n\to\infty} \sup_{x \in C(\epsilon,r)} |\mathcal{I}_{\{f_n(x)=k\}} - \mathcal{I}_{\{f(x)=k\}}| = 0 \text{ a.s., for } k = 1, \ldots, K,$$

where $C(\epsilon, r) = A(\epsilon) \cap B(0, r)$ stands for the intersection of the set $A(\epsilon)$ and the closed ball centered at zero of radius ϵ, $B(0, r)$.

b)

$$d(X, \partial G_k^n) - d(X, \partial G_k) \to 0 \text{ a.s., for } k = 1, \ldots, K,$$

where $d(X, \partial G_k)$ stands for the distance from X to the frontier of G_k.

Assumption 2:

$$\lim_{\delta\to 0} P(d(Y, \partial G_k) < \delta) = 0, \text{ for } k = 1, \ldots, K.$$

Assumption 1a holds typically for cluster and classification rules, where the set $A(\epsilon)$ is the complement of an ϵ–neighborhood ("outer parallel set") of the partition boundaries as shown in Figure 1, i.e.

$$A(\epsilon)^c = \bigcup_{x \in \cup_{k=1}^K \partial G^k} B(x, \epsilon),$$

where $B(x, \epsilon)$ denotes the ball with center x and radius ϵ.

Theorem 1 (Strong Consistency) *Let $\{X_j : j \geq 1\}$ be iid random vectors with distribution P_X. Given d, $1 \leq d < p$, let I_d be the family of all subsets of $\{1, \ldots, p\}$ with cardinal d, and $I_{d,0} \subset I_d$ the family of subsets where the*

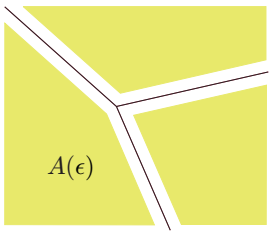

Figure 1: Excluding a neighborhood of the partition boundaries, we have almost sure uniform convergence of the function f_n to f over compact sets (the color area $A(\epsilon)$).

maximum of $h(I)$ is attained, for $I \in I_d$. Then, under assumptions 1 and 2 we have that there exists $n_0 = n_0(\omega)$, such that

$$I_n \in I_{d,0} \text{ for } n \geq n_0(\omega) \text{ a.s.}$$

The proof is given in the Appendix.

2.3 Selection of variables in simulated data

In order to analyze our method performance, we carry out a Monte Carlo study for some simulated date sets. In all of them we generated 100 observations in a three dimensional variable space. The underlying distributions are mixtures of three multivariate normals,

$$\boldsymbol{X} = \begin{pmatrix} X_1 \\ X_2 \\ X_3 \end{pmatrix} \sim \sum_{i=1}^{3} \alpha_i \mathcal{N}_3 \left(\boldsymbol{\mu}_i, \boldsymbol{\Sigma}_i \right),$$

where $\alpha_1 = \alpha_2 = 0.35$ and $\alpha_3 = 0.30$. The cluster structure is defined through X_1 and X_2 and, to simplify, we consider they are independent in all the cases, with distributions given by

$$X_1 \sim \alpha_1 \mathcal{N}(0, 0.2) + \alpha_2 \mathcal{N}(0.1, 0.2) + \alpha_3 \mathcal{N}(0.9, 0.2)$$
$$X_2 \sim \alpha_1 \mathcal{N}(0, 0.2) + \alpha_2 \mathcal{N}(0.9, 0.2) + \alpha_3 \mathcal{N}(0.1, 0.2).$$

For the distribution of X_3 we consider two different scenarios.

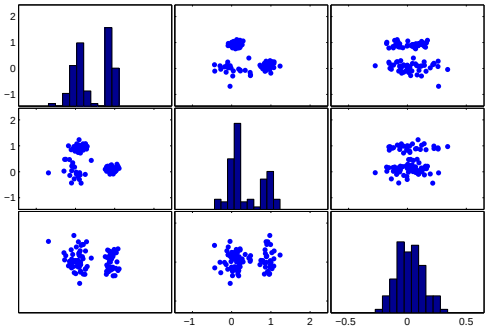

Figure 2: Scatter plots and histograms from a three dimensional data set generated following Case I description with $\sigma = 0.2$

Case I: X_3 is an independent "noise" variable with distribution given by

$$X_3 \sim \mathcal{N}(0, \sigma),$$

where σ takes different values, 0.1, 0.2 and 0.3. Figure 2 shows a simulated data set from these distributions with $\sigma = 0.2$. The three clusters are perfectly distinguish when plotting the pairs (x_1, x_2), however only two clusters are appreciated in the scatter plots that consider X_3, as it is the case of the X_1 and X_2 histograms.

Case II: X_3 is not an independent variable and is given by

$$X_3 = (X_1 + X_2)/\sqrt{2}.$$

In Table 1 we report the proportion of times where the information in only one, two or three variables is enough to explain all the cluster allocations. We also consider the effect of a possible reduction in the efficiency to only 95%, or 90%, of correct allocations. In all the cases we carried out 1,000 replications and follow the next steps.

1. Generate $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_{100}$ observations.
2. Split the data into three cluster using the k–means algorithm.
3. Search the optimal subset of variables for 100%, 95% and 90% efficiencies.

			Number of variables		
		Efficiency	1	2	3
$X_3 \sim \mathcal{N}(0, \sigma)$	$\sigma = 0.1$	100%	0	0.997	0.003
		95%	0.005	0.995	0
		90%	0.008	0.992	0
	$\sigma = 0.2$	100%	0	0.926	0.074
		95%	0.003	0.986	0.011
		90%	0.005	0.994	0.001
	$\sigma = 0.3$	100%	0	0.736	0.264
		95%	0	0.976	0.024
		90%	0.006	0.988	0.006
$X_3 = (X_1 + X_2)/\sqrt{2}$		100%	0	0.146	0.854
		95%	0.001	0.970	0.029
		90%	0.003	0.990	0.007

Table 1: Simulation results from the Monte Carlo study carried out using the distributions proposed in cases I and II

In the first case our variable selection method is very successful and selects only the two variables X_1 and X_2 in almost all the simulations, for 100%, 95% and 90% efficiencies. A different scenario appears with case II, where the third variable is a linear combination of the first two variables. Only in the 14.6% of the times the two variable subset explains all the cluster allocations. This changes dramatically when we allow for a 5% or 10% of miss–classified observations, now 97% of the times the method selects only two variables, instead of three.

Case II shows and interesting feature of the selection variable procedure, it is able to eliminate noise variables, but it is unable to detect redundant information from co–linear variables. This effect can be more clearly seen with the simulated example proposed by Tadesse, Sha and Vannucci (2005). The data consists on the 15 three-dimensional observations displayed in Figure 3a. The first four observations come from independent normals with mean $\mu_1 = 5$ and variance $\sigma_1^2 = 1.5$. The next three data come from independent normals with mean $\mu_2 = 2$ and variance $\sigma_2^2 = 0.1$. The following six data come from independent normals with mean $\mu_3 = -3$ and variance $\sigma_3^2 = 0.5$,

Figure 3: a) Dots are the simulated data TSV05 as in Tadesse *et al.* (2005) and stars are the four k-means centers, b) results of blinding the vertical coordinate with the mean value.

while the last two come from independent normals with mean $\mu_4 = -6$ and variance $\sigma_4^2 = 2$. Despite in Tadesse *et al.* (2005) the data set was generated with twenty–dimensional observations instead of three–dimensional, we call TSV05 to this data set.

We first run the k-mean algorithm with $k = 4$, which classified correctly the whole data set. Then, we run the variable selection procedure based on the mean value (dropping out noisy non–informative variables). A closer look to this data generating mechanism indicates that one should expect to attain a 100% efficiency with only one variable, since we have the same cluster structure at the three coordinates. However, the procedure was unable to find the cluster structure blinding all variables except one. The efficiencies in Table 2 show that only the subset with the three variables classify all the data in their original clusters. This result is expected since all the variables contain information about the cluster, they are not noisy variables. However, as in case II, these colinear variables are redundant and would be interesting to develop a variable selection method able to detect them.

Figure 3b helps us to understand the main problem that appears when we blind one variable by substituting all the data for the mean value. We observe the case of blinding the vertical coordinate, that means a projection of all the data in the shadow mean plane. As the mean is not a representative value for data generated from a cluster structure, the allocations will be by chance to any of the clusters. For instance, we point out the correct center for one projected data with a discontinuous arrow, however in this

Subset	X_1	X_2	X_3	X_1, X_2	X_1, X_3	X_2, X_3	X_1, X_2, X_3
Efficiency	60%	60%	60%	66.66%	73.33%	86.66%	100%

Table 2: Percentage of correct allocations in the TSV05 data set using the variable selection method based on the mean.

case the closer center is a different one. This data is wrongly allocated with the variable selection method. Remember that we blind the variable but not the corresponding coordinate of the k-mean centers. Then to eliminate not only noisy variables but also colinear variables the idea is to blind with local information, instead of using the mean. This would not be a problem for noisy variables and we will see in the next section that it is crucial for multicolinearity.

3 Dealing with multicolinearity

The previous procedure is mainly designed to find "noisy" non-informative variables, however as the simulated data set highlighted, it may fail in the presence of colinearity. In order to deal with this problem, we consider a quite natural extension, changing the definition of the "less informative" vector Y^I. Recall that we defined $Y_i^I = X_i$, if $i \in I$, and $Y_i^I = E(X_i)$ otherwise. Thus, for indices in the complement of the set I, Y_i^I is defined as the best constant predictor. Now the idea appears clearly, to change means by conditional means. We define the less informative vector Z^I for indices i in the complement of the set I as the conditional expectation of X_i given the set of variables $\{X_l : l \in I\}$, i.e. the best predictor of X_i based on those variables. This procedure will be able to deal with both kinds of problems. However, at a first look, a shortcoming is that it will require a large sample size in order to estimate the conditional expectation. Also the computational effort is quite bigger. The choice of the smoothing parameter is also challenging, since it must involve not more data than the size of the smaller cluster (if we think for instance in local averages). If m_n is the size of the smallest group for the partition procedure, and for each d and n, $r = r(n, d)$ is the number of nearest neighbor's we will need to require that $r < m$, together

with the standard conditions $r/n \to 0$, and $n(r/n)^d \to \infty$, as $n \to \infty$. We now describe briefly the proposal in a precise setup.

3.1 Population and empirical objetive function

Given a subset of indices

$$I = \{i_1 \ldots, i_d\} \subset \{1, \ldots, p\},$$

let

$$X[I] =: (X_{i_1}, \ldots, X_{i_d}), \text{ for } i_1 < i_2 < \ldots < i_d.$$

We define the vector $Z^I := Z = (Z_1, \ldots, Z_p)$, where $Z_i = X_i$ if $i \in I$ and $Z_i = E(X_i|X[I])$ otherwise. Instead of the conditional expectation $E(X_i|X[I])$ in order to attain robustness we can use local medians, or local M-estimates (see for instance, Stone, 1977, Truong, 1989 or Boente and Fraiman, 1995).

For a fix integer $d < p$, now the *population objective function* is the set $I \subset \{1, \ldots, p\}$, $\#I = d$, for which the function

$$h(I) = \sum_{k=1}^{K} P\left(f(X) = k, f(Z^I) = k\right),$$

attains it maximum.

In practice, the empirical version consists on the same steps than in the method based on using the mean, except the second, that is substitute by the next step:

2'. For a fixed value of $d < p$, given a subset of indices $I \subset \{1, \ldots, p\}$, with $\#I = d$, fix an integer value r (the number of nearest neighbor to be used). For each $j = 1, \ldots, n$, find the set of indices C_j of the r-nearest neighbor's of $X_j[I]$ among $\{X_1[I], \ldots, X_n[I]\}$.

Now define the random vectors $\{X_j^*, 1 \leq j \leq n\}$ verifying

$$X_j^*[i] = X_j[i] \text{ if } i \in I, \text{ and } X_j^*[i] = \frac{1}{r} \sum_{m \in C_j} X_m[i] \text{ otherwise,}$$

where $X[i]$ stands for the i–coordinate of the vector X.

A resistant procedure would take the local median instead of the local mean for $i \notin I$, i.e. $X_j^*[i] = median(\{X_m[i] : m \in C_j\})$.

3.2 Consistency. Assumptions and main result

As we have seen before the consistency of the variable selection method relays on the properties of the cluster partition methods. Moreover, regularity conditions on the boundary of the partitioning sets, in order to carry out the nonparametric regression, are requested. Now, we give the conditions under which our procedure is consistent. Together with Assumption 1 we will need:

Assumption 3:

$$\lim_{\delta \to 0} P(d(Z, \partial G_k) < \delta) = 0, \text{ for all } k = 1, \ldots, K.$$

Assumption 4:

$$\sup_x |g_{i,n}(x) - g_i(x)| \to 0 \ a.s., \text{ for i } \notin I$$

where $g_i(x) = E(X_i|X(I) = x)$ is the corresponding non–parametric regression functions and $g_{i,n}(x)$ is a consistent estimate of $g_i(x)$.

Assumption 4 allows to use any uniformly consistent estimate of the regression function, although we have only describe above the case of r–nearest neighbor estimates.

Theorem 2 (Strong Consistency) *Let $\{X_j : j \geq 1\}$ be iid random vectors with distribution P_X. Given d, $1 \leq d < p$, let I_d be the family of all subsets of $\{1, \ldots, p\}$ with cardinal d, and $I_{d,0} \subset I_d$ the family of subsets where the maximum of $h(I)$ is attained, for $I \in I_d$. Then, under assumptions 1, 3 and 4 we have that there exists $n_0 = n_0(\omega)$, such that*

$$I_n \in I_{d,0} \text{ for } n \geq n_0(\omega) \ a.s.$$

The proof of Theorem 2 is very similar to that of Theorem 1 and we omit it in full detail. We only point out the differences at the Appendix.

3.3 TSV05 example revisited

When we apply the conditional mean selection variable method to the 15 three dimensional data of TSV05, we now obtain that with only one variable we attain a 100% efficiency. This is the case of the second or the third variable, while with the first one we obtain a 93.3% efficiency.

A slightly different version of this example includes three new variables. The additional noisy coordinates are generated from independent standard normal distributions. The two variable selection procedures applied to the six–dimensional data set produce exactly the same results as for the three dimensional data. The noisy variables are not necessary to reach 100% efficiency.

4 A forward–backward algorithm

A well known feature of the variable selection problem is the great number of subsets that should be considered even for moderate values of p. An exhaustive search guarantees to find the smaller subset of variables to achieve, at least, a fixed percentage on the empirical objective function, however this procedure is non feasible when many variables are considered. For instance, if $p = 50$ we should check among more than 10^{15} combinations. Alternatively, we propose a computationally less expensive forward-backward search algorithm. We run the search meanly in the forward mode and include the last step in the backward mode.

The algorithm starts from a one variable set and, progressively, includes new variables with an iterative revision of the inclusions in each step. In general, the backward search is less costly, but the leave-one-out strategy will make difficult to find a small subset. When a set provides a percentage of good classifications over the fixed percentage, the backward process starts the search of a more parsimonious solution. To compute the objective function we can blind the variables either replacing them by the mean or the conditional mean (in this case the conditional distribution is towards the chosen subset

up to that step). The estimation of the conditional mean is done by nearest neighbors.

We distinguish three parts in the algorithm design, that are sequentially implemented.

Part 1: Select the most "influential" variable $X^{(1)}$ (the data assignation is more affected by its absence), blinding one by one all the variables and selecting the one with minimum value of the objective function,

$$X^{(1)} = \arg \min_{1 \leq j \leq p} h_n \left(I_j \right),$$

where I_j denotes all the variables except the j^{th}, that is blinded.

Part 2: Sequential increment of variables one by one (forward search). In each step we look for the accompanying variable, such that the new subset maximizes the number of successfully data allocations. We also consider replacement of previously introduced variables following the iterative scheme described by Miller (1984) as a variation of the classical forward-backward methods. The increment continues until the fixed percentage of well classified data is reached.

Part 3: The subset is revised for unnecessary variables (backward search). The previously introduced variables are questioned one by one whether they are necessary. The algorithm stops when no further reduction can be found without loss of efficiency.

This procedure strongly depends on the order in the variable vector. To avoid (or minimize) the label effect we run the algorithm for a random sample of the permuted variables. We finally select the solutions that use the minimum number of variables.

In the following section we illustrate the algorithm performance in real data examples. The matlab codes are available upon request to the authors.

5 Real Data Examples

5.1 Evaluation of educational programs

We have survey data concerning education quality from 98 schools in the city and suburbs of Buenos Aires (Argentine). The survey and posterior data analysis was developed by Llach *et al.* (2006). An important objective on this study was to find homogeneous groups of schools and the characterization of the clusters. The selection variable method is a powerful tool to separate all the variables with real influence from those that are non-informative.

At each school, a questionnaire with fifteen items was fulfilled by the headmaster and the teachers. The questions regard on the human and didactic resources, the relationships between all the involved agents and the building physical condition. All the answers range in a discrete scale between 1 and 100. The items V_1 to V_8 are answered by the headmasters and refer to their experience, aptitude, school general knowledge, evaluation of the building conservation, evaluation of the didactic resources, relationships with teachers, parents and students. The items V_9 to V_{15} are answered by the teachers and the questions are the same V_1 to V_8, except V_3 (school general knowledge) that is only answered by the headmasters.

In Llach *et al.* (2006), a k–means cluster procedure was performed using the 98 fifteen dimensional vectors. The data were split into three clusters of sizes 45, 21 and 19 respectively.

The relationship between the clusters and the mean scores in a general knowledge exam (GKE) and the mean socioeconomic level of the students (SEL) are shown in Table 3. Both the GKE results and SEL are significatively different among clusters, with ANOVA $p-$values $\ll 0.0001$. The clusters with higher mean level of student knowledge correspond with those with also higher mean socioeconomic level. The question now is which variables have relevant information to establish this school grouping.

We select the variables that determine the clusters according to the first proposal, with an exhaustive search (it is possible because of the moderate di-

	GKE		SEL	
	Mean	Std	Mean	Std
Cluster 1	49.25	9.18	49.51	9.93
Cluster 2	58.04	13.01	63.49	16.39
Cluster 3	64.60	10.94	68.80	11.79

Table 3: Means and standard deviations for the student general knowledge exams (GKE) and the student socioeconomic levels (SEL).

mension of the data). The clusters are completely explained (100% efficiency) by $V_3, V_4, V_7, V_8, V_{11}, V_{12}, V_{14}, V_{15}$, that are headmaster's school general knowledge, evaluation of the building conservation, relationships with parents and students, and teacher's evaluation of the building conservation, evaluation of the didactic resources, relationships with parents and students.

As the requested efficiency decays, so does the number of variables, the subset includes the variables $V_1, V_4, V_7, V_{11}, V_{12}, V_{14}$ for 98% efficiency. For 95% efficiency several subsets of size six were found. To achieve 92% efficiency, we found two optimal subsets with only four variables V_4, V_7, V_{11}, V_{14} or V_4, V_7, V_{12}, V_{14}, that are headmaster's evaluation of the building conservation, relationships between headmasters and parents, and between teachers and parents. The elective variables are teacher's evaluation of the building conservation or teacher's evaluation of the didactic resources In all the cases the subsets contain information from the headmasters and the teachers.

With the aim of studying the algorithm performance we run it with 100 permutations and the results were consistent with the exact procedure. We found almost all the subsets that were found before.

To refine the previous results we apply the conditional procedure to detect colinearity. When we apply either the exact procedure or the algorithm we found the same subsets, variables $V_2, V_3, V_4, V_7, V_8, V_{11}, V_{12}, V_{14}$ or $V_3, V_4, V_7, V_8, V_9, V_{11}, V_{12}, V_{14}$ reach 100% efficiency. For 97% efficiency the variables founded are $V_3, V_4, V_7, V_{11}, V_{14}$, and only three variables V_4, V_7, V_{14} are requested to explain 91% of the cluster allocations. These final variables include headmaster's evaluation of the building conservation, relationship

between headmasters and parents, and between teachers and parents.

All over the data analysis we observe the importance of the relationships with the parents, both with the headmasters and teachers. When we look for non–noisy variables we found that also relationships with students have relevant information about the cluster origin. However, these variables are eliminated from the final subset when we use the conditional mean, this means that the opinion about the relationships with the students contains redundant information.

5.2 Identifying types of electric power consumers with functional data

We consider the same example presented in Cuesta–Albertos and Fraiman (2006), where an impartial–trimming cluster procedure is proposed for functional data. The study was oriented to find behavioral patterns of the electric power home–consumers in the City of Buenos Aires. For each home, measurements were taken every 15 minutes during all the weekdays of January 2001. The analyzed data were the vectors of dimension 96 with the monthly averages for a sample of 101 home–consumers. The data were normalized in such a way that the maximum of each curve was equal to one. Cuesta–Albertos and Fraiman (2006) found a two clusters structure, 13 outliers apart. The resulting trimmed 2–mean functions (cluster centers) are shown in Figure 4. Then the non-trimmed functions were assigned to the closest center and with this criteria the first cluster is composed of 33 home-consumers and the second one of 55. The remaining 13 data have been considered as outliers.

In this example, the set of variables includes all the electricity consumptions in the 15 minutes time–intervals in a day, that is 96 variables. A number too large for the computation of the exact objective functions in all the possible subsets. Therefore, in order to find the more relevant "windows–times" for the cluster procedure we need to run the forward-backward search algorithm. We apply both the mean and the conditional mean selection of variable algorithms for a 90%, 95% and 100% of efficiency. For the calcu-

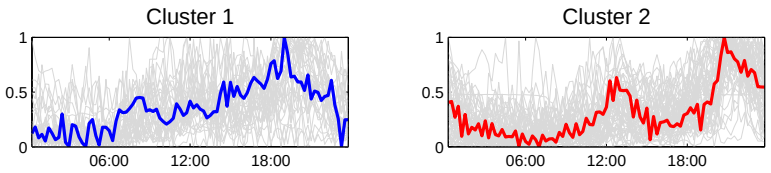

Figure 4: Home-consumers and cluster centers (α-2-mean functions with trimming proportion $\alpha = 13/101$), of the two cluster structure for the electricity consume functional data.

lation of the conditional mean, we consider 5, 10 and 33 nearest neighbor's (NN). The results after 100 permutations are summarized in Table 4.

The use of the conditional mean algorithm, instead of the faster mean algorithm, reduces in all the cases the number of time–intervals that provides enough information to characterize the two electric power home–consumer typologies. The results show that the choice of the number of nearest neighbor's is also important, although the method seems to be less sensitive than non–parametric regression. However, it is an important problem to be solved. In our case, the results for 5-NN are quite satisfactory: for a 100% of efficiency, there is only one solution with 9 variables; for a 95% of efficiency we found 15 different solutions with six variables; while for a 90% of efficiency we found 5 different solutions with four variables. We choose one of them to illustrate in Figure 5 the "window–times" (non-shadow areas) which seems relevant.

The most informative consume registers are confined to a few "window–times" (see Figure 6) and the two types of electric power consumers are mainly characterized by their different aptitudes at some time–intervals in the morning (7:00 to 11:00), evening (15:00 to 19:00), night (21:00 to 24:00) and early morning (3:00 to 4:00). Comparing the mean and the 5-NN conditional solutions we observe that the redundant information, specially at evening and night, is summarized in the smaller subset of variables found by the mean conditional algorithm. When we reduce the degree of efficiency and

NN	Effic.	num. of variables	Effic.	num. of variables	Effic.	num. of variables
5	90%	4	95%	6	100%	9
10		3		5		16
33		3		7		28
Mean	90%	15	95%	22	100%	33

Table 4: Optimal number of variables (time–intervals) for different efficiency percentages and number of nearest neighbor's using both the mean and the conditional mean selection of variable algorithms.

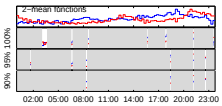

Figure 5: Two–mean electricity consume cluster centers for the functional data. Non–shadow time–intervals correspond to the subset of variables found by the 5-NN Conditional Mean Algorithm, with different degrees of efficiency.

accept a number of missclassifications, the importance of the early morning behavior diminished.

6 Final Remarks

We propose two variable selection procedures particularly design for partition rules (typically supervised and un-supervised classification methods) that help to understand the results for high-dimensional data. Both methods are strongly consistent. The second procedure, based on conditional means, is much more flexible and takes into account general dependence structures within the data. The performance of our proposals in simulated and real data examples is quite impressive.

For low or moderate dimensional data an exhaustive search is possible for even the case of 100% efficiency. However, it is unfeasible for high-dimensional data and we propose a forward-backward algorithm. We compare the algorithm performance with the exhaustive search in some of the examples and the results are very positive since they provide the same subsets. However, it will demand a considerable computational effort in time

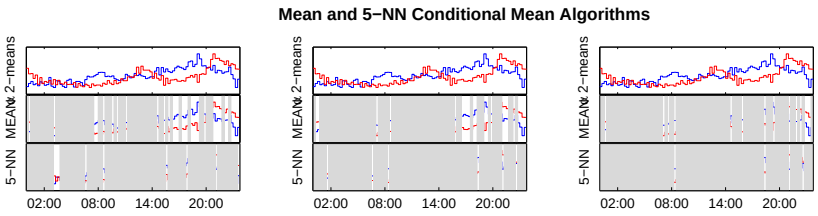

Figure 6: Two–mean electricity consume cluster centers for the functional data. Non–shadow time–intervals correspond to the subset of variables found by the Mean and the 5-NN Conditional Mean Algorithms, for different degrees of efficiency.

that suggest that some additional research should be consider in this aspect.

Appendix

Proof of Theorem 1

To simplify the proof, we assume that there exists a unique subset $I_{d,0} =: I_0 = \{i_1, \ldots, i_d\} \subset \{1, \ldots, p\}$ that maximize $h(I)$ for $I \in I_d$. Then we point out the differences with the case of more than one subset along the lines of the proof.

As the optimization is over all the d combinations of the p variable indices, a finite number, it suffices to show that

$$\lim_{n\to\infty} h_n(I) = h(I) \text{ a.s., for all } I \in I_d. \tag{1}$$

Indeed, since there exist a unique set $I_0 \in I_p$ that maximizes $h(I)$, there exists $\eta > 0$ such that

$$h(I_0) > h(I) + \eta \ \text{, for all } I \neq I_0, I \in I_p.$$

We have from (1) that for all $I \in I_p$

$$|h_n(I) - h(I)| < \frac{\eta}{2}, \ \text{ if } \ n \geq n_0(I, \omega),$$

which entails

$$h_n(I) < h(I) + \frac{\eta}{2} < h(I_0) - \frac{\eta}{2}, \ \text{ if } \ I \neq I_0. \tag{2}$$

Since we also have

$$h_n(I_0) > h(I_0) - \frac{\eta}{2} > h(I) - \frac{\eta}{2},$$

we conclude that I_0 maximizes $h_n(I)$ if $n \geq n_0(w)$ a.s.

If there exists more than one subset in $I_{d,0}$, the argument is the same by replacing I_0 by $I_{d,0}$.

Now, it remains to show (1), which reduces to prove that

$$\lim_{n\to\infty} \frac{1}{n} \sum_{j=1}^{n} \mathcal{I}_{\{f_n(X_j)=k\}} \mathcal{I}_{\{f_n(X_j^*)=k\}} = P(f(X) = k, f(Y) = k) \text{ a.s.}, \tag{3}$$

for $k = 1, \ldots, K$.

Finally, the equation (3) will follow if we show that, for all fixed k,

$$\lim_{n\to\infty} \frac{1}{n} \sum_{j=1}^{n} \mathcal{I}_{\{f_n(X_j)=k\}} \mathcal{I}_{\{f_n(Y_j)=k\}} = P(f(X) = k, f(Y) = k) \text{ a.s.} \tag{4}$$

and

$$\lim_{n\to\infty} \frac{1}{n} \sum_{j=1}^{n} \mathcal{I}_{\{f_n(X_j)=k\}} [\mathcal{I}_{\{f_n(X_j^*)=k\}} - \mathcal{I}_{\{f_n(Y_j)=k\}}] = P(f(X) = k, f(Y) = k) \text{ a.s.} \tag{5}$$

First we show that by the Assumption 1a we have

$$lim_{n\to\infty} \frac{1}{n} \sum_{j=1}^{n} \mathcal{I}_{\{f_n(X_j)=k\}} \mathcal{I}_{\{f_n(Y_j)=k\}} - \mathcal{I}_{\{f(X_j)=k\}} \mathcal{I}_{\{f(Y_j)=k\}} = 0 \text{ a.s..} \tag{6}$$

The left hand side of (6) is majorized by

$$\frac{1}{n} \sum_{\{X_j \in C(\epsilon,r)\} \cap \{Y_j \in C(\epsilon,r)\}} |\mathcal{I}_{\{f_n(X_j)=k\}} \mathcal{I}_{\{f_n(Y_j)=k\}} - \mathcal{I}_{\{f(X_j)=k\}} \mathcal{I}_{\{f(Y_j)=k\}}| +$$

$$\frac{1}{n} \sum_{\{X_j \notin C(\epsilon,r)\} \cup \{Y_j \notin C(\epsilon,r)\}} |\mathcal{I}_{\{f_n(X_j)=k\}} \mathcal{I}_{\{f_n(Y_j)=k\}} - \mathcal{I}_{\{f(X_j)=k\}} \mathcal{I}_{\{f(Y_j)=k\}}|$$

The first term converges to zero for any ϵ and r by Assumption 1a, while the second term is dominated by

$$\frac{1}{n} \#\{1 \leq j \leq n : \{X_j \notin C(\epsilon, r) \cup \{Y_j \notin C(\epsilon, r)\}\}$$

which converges a.s. to

$$P((\{X \notin C(\epsilon, r) \cup \{Y \notin C(\epsilon, r)\}).$$

Since this last limit can be made arbitrarily small choosing ϵ and r adequately, (6) holds. Finally from the Law of Large Numbers we get

$$\lim_{n\to\infty} \frac{1}{n} \sum_{j=1}^{n} \mathcal{I}_{\{f(X_j)=k\}} \mathcal{I}_{\{f(Y_j)=k\}} = P(f(X) = k, f(Y) = k) \text{ a.s.},$$

which concludes the proof of (4).

For the proof of the equation (5), the way in which the random vectors X_j^* and Y_j have been defined, for a fixed subset I, implies that all the i–coordinates of $X_j^* - Y_j$ are zero for $i \in I$, while the rest of them (for $i \notin I$) are given by

$$\bar{X}[i] - E(X[i]).$$

We recall that $X[i]$ stands for the i–coordinate of the vector X, and $\bar{X}[i] = \frac{1}{n} \sum_{j=1}^{n} X_j[i]$.

The vectors $X_j^* - Y_j$ are all the same (i.e. the difference do not depend on j), and are given by

$$(X_j^* - Y_j)[i] = (\bar{X}[i] - E(X[i]))\mathcal{I}_{\{i \notin I\}}, \text{ for } j = 1, \ldots n. \tag{7}$$

¿From the Law of Large Numbers we get

$$\max_{j=1,\ldots,n} ||X_j^* - Y_j|| \to 0 \text{ a.s.}$$

The proof of (5) will be complete if we show that

$$\#\left\{j : f_n(X_j^*) = k, f_n(Y_j) \neq k, f_n(X_j) = k\right\}/n \to 0 \text{ a.s.}, \tag{8}$$

and

$$\#\left\{j : f_n(Y_j) = k, f_n(X_j^*) \neq k, f_n(X_j) = k\right\}/n \to 0 \text{ a.s.} \tag{9}$$

We now define the sets B and C as follows:

$$B = \left\{\omega \in \Omega : \max_{j=1,\ldots,n} ||X_j^* - Y_j|| \to 0\right\},$$

$$C_j = \left\{\omega \in \Omega : d(X_j, \partial G_k^{(n)}) - d(X_j, \partial G_k) \to 0\right\}$$

and

$$C = \bigcap_{j=1}^{\infty} C_j.$$

By the Assumption 1b we have that $P(B \cap C) = 1$. Therefore, given $\delta > 0$ and $\omega \in B \cap C$, there exists $n_0 = n_0(\omega, \delta)$ such that

$$max_{j=1,\ldots,n}||X_j^* - Y_j|| \leq \delta/2.$$

Given $\omega \in B \cap C$, we also have the following inclusions:

$$\begin{aligned}\left\{j : f_n(X_j^*) = k, f_n(Y_j) \neq k, f_n(X_j) = k\right\} &\subset \left\{j : d(X_j^*, \partial G_k^{(n)}) < \delta\right\} \\ &\subset \left\{j : d(Y_j, \partial G_k) < 2\delta\right\},\end{aligned}$$

which imply that the left hand side of (8) is majorized by

$$\#\left\{j : d(Y_j, \partial G_k) < 2\delta\right\}/n \leq \frac{1}{n}\sum_{j=1}^{n} \mathcal{I}_{\{d(Y_j, \partial G_k) < 2\delta\}},$$

which converges, as $n \to \infty$, to

$$P(d(Y, \partial G_k) < 2\delta).$$

Finally, from the Assumption 2 we get that

$$\lim_{\delta \to 0} P(d(Y, \partial G_k) < 2\delta) = 0,$$

which concludes the proof of (8). The proof of (9) is completely analogous.

Proof of Theorem 2

The proof goes on the same lines as the proof of Theorem 1. The only difference is that now

$$\max_{j=1,\ldots,n} ||X_j^* - Z_j|| \to 0 \text{ a.s.}$$

follows from Assumption 4.
